Soft Switching Converter Using Current Shaping

Background of Invention

1. *Field of the Invention*

- This invention relates to DC-to-DC converters, DC-to-AC inverters and AC-to-DC converters. 5 The major characteristic of this power conversion technique is that primary switching elements switches at zero voltage and the secondary rectifiers means have negligible reverse recovery losses.

2. *Description of the Prior Art*

There is a continuing industry demand for increasing power density, which means more power transferred in a given volume. A method for increasing the power transfer through the converter is to increase the switching frequency in order to minimize the size of the transformer and the capacitors. Using prior art topologies such as forward or flyback, which employ "hard" switching techniques, makes high frequency operation less efficient. The switching losses associated with switching elements, which turn on when there is a voltage across them, are proportional with the switching frequency. An increase in switching frequency leads to an increase in switching losses and an increase in level of electromagnetic interference (EMI).

In order to overcome limitations in switching speeds, the prior art has devised a new family of soft transition. The U.S. patent Nos. 5,132,889, 5,126,931, 5,231,563, 5,434,768 present several methods of accomplishing zero voltage switching across the primary switches.

Another power loss mechanism is due to the reverse recovery in the output rectifiers. During 20 switching when a negative polarity voltage is applied to a rectifier that is in conduction, the current through the rectifier will continue to conduct until all the carriers in the rectifier's junctions are depleted. During this period of time the current polarity will reverse the current flowing from the cathode to the anode, while the voltage across the diode is still positive from the anode to the cathode. The current flowing in reverse through the diode will reach a peak value referred in literature as I_{rrm} . Further on,

while the rectifiers' junction is depleting the carriers, the rectifier becomes a high impedance device. The current through the rectifier will decrease rapidly from I_{Rm} level to zero. During the same time the negative voltage across the rectifier will build up to high levels.

5 During the period of time when there is a negative voltage across the diode and negative current is flowing through it, there will be power dissipation in the device. This kind of loss is referred in the literature as reverse recovery losses. The reverse recovery loss is proportional with the reverse recovery current I_{Rm} , the negative voltage across the rectifier and the frequency.

The reverse recovery current I_{Rm} , which is a key component in reverse recovery loss, is a function of the type of device, the temperature and the current slope at turn off. The reverse recovery characteristics are worse for higher voltage rectifiers. As a result the reverse recovery loss becomes a significant loss mechanism for higher output voltage applications. The reverse recovery current I_{Rm} is directly dependent on the current slope at turn off. A soft slope reduces the reverse recovery current and as a consequence reduces the reverse recovery loss. To accomplish a very soft slope current at turn off an inductive element has to be in series with the rectifier. The inductor element will prevent a fast current variation dI/dt . The presence of an inductive element in series with the rectifier will increase the negative voltage across the rectifier at turn off. The reverse voltage across the rectifier can reach very high levels and can exceed the voltage break down of the device, leading to failure.

RC snubbers or complicated lossless snubbers can be added across the rectifier to reduce the reverse recovery loss and the voltage stress on the devices. This leads to complex circuits and this 20 negatively affects the efficiency and the reliability. As a result of these limitations the high voltage converters have to operate at lower frequency in order to reduce the power dissipation associated with reverse recovery.

In Fig. 2A is presented a standard full bridge phase shifted topology. The primary switching elements, M1, M2, M3 and M4 are controlled as depicted in the key waveforms of Fig. 2B. During the 25 time M1 and M4 are conducting there is a positive voltage at the dot in the secondary winding and the

rectifier D1 is conducting. When M4 turns off in the primary winding the current will continue to conduct and its path will be through the parasitic capacitance of M3 and M4, discharging the parasitic capacitance across M3 to zero and as a result creating zero voltage switching conditions. As a result M3 will turn on at zero voltage. Further M1 and M3 will be conducting. During this time the primary winding of the transformer is shorted and the voltage in the secondary winding is zero. Both D1 and D2 will conduct during this time. The current through Lo will be split equally between D1 and D2.

At the moment when M1 turns off, the current will continue to flow in the primary discharging the parasitic capacitance of M2 towards zero. If certain conditions are met, M2 will turn on at zero voltage conditions. In any event, when M3 and M2 conduct the polarity will change in the secondary winding. The change in polarity will force the current flowing through Lo to flow totally through D2 and the rectifier D1 will be reverse biased. Due to the reverse recovery characteristic of D1 the current will flow in reverse through D1 until the carriers in the junction are depleted. After that the rectifier D1 will behave as a high impedance device. As a function of the current slope through D1 at turn off, which determines the reverse recovery characteristics of D1, and as a function of the parasitic inductive elements in series with D1, large voltage spikes will develop across D1 as shown at 10 in Fig. 2B. This phenomenon will lead to reverse recovery losses in D1, when the reverse recovery current and reverse voltage will be present on the rectifier. In addition, these large voltage spikes developed across D1 may lead to voltage stress, which may exceed the rating of the device. For this reason snubbing circuits may have to be employed across D1, which will increase the power dissipation, increase circuit complexity, 20 decrease reliability and decrease power density. The reverse recovery current associated with D1 will also create a "temporary short" across the secondary winding, preventing the resonant transition across M2 from achieving zero voltage switching conditions. The voltage ringing across D1 will also lead to increased EMI.

The losses associated with the reverse recovery of the output rectifiers are proportionate with the 25 frequency. The trend towards miniaturization requires an increase in switching frequency, which will

lead to more reverse recovery losses. In order to accomplish miniaturization, higher efficiency is necessary to minimize heat. In conclusion we need a topology wherein the reverse recovery losses shall be eliminated, in this way allowing an increase in switching frequency without a penalty in efficiency.

Brief Summary of the Invention

5 This invention presents a circuit technique designed to reduce the negative impact of the reverse recovery in the rectifiers, while allowing zero voltage switching on the primary switching elements. This technique works by forcing the current out of the rectifier before a reverse voltage is applied to it. This method operates by shaping the current through the output rectifiers using an additional AC voltage source superimposed on the main AC voltage induced in the secondary winding by the primary winding. In this implementation the reverse recovery losses in the rectifiers are totally eliminated, though the converter operates in continuous conduction mode. Another major advantage of the proposed circuit is the fact that the current reflected in the primary is shaped to a trapezoidal form with a low dI/dt during the turn on of the primary switchers. This will allow the completion of the resonant transition to zero voltage across the primary switching elements.

The above and further objects and advantages of the invention will be better understood from the following detailed description of at least one preferred embodiment of the invention, taken in consideration with the accompanying drawings.

Brief Description of the Drawings

Figure 3B is a timing diagram of the circuit of Fig. 3A; and

Figure 4 is a schematic diagram of a further specific embodiment of a converter configured in accordance with this invention.

Detailed Description

The present invention addresses the goal of eliminating the reverse recovery losses, while maintaining continuous conduction mode in the output choke. The general concept is described in connection with Fig. 1A. It consists in adding an additional AC voltage source, which will generate a low voltage square waveform signal.

In Fig. 1A is presented a simplified schematic and in Fig. 1B is presented key waveforms for the technology according to this invention. The circuit is based on a typical full bridge phase shifted topology, with an additional low voltage AC source 15 placed in series with a primary winding 16.

In Fig. 1B the conventional control signals for the primary switching elements M1, M2, M3 and M4 are also depicted. The injected AC voltage will alter the voltage in the secondary of the transformer as is depicted by the dotted lines in Fig. 1B, Vsec.

During the time wherein M1 and M4 are conducting the voltage induced in the secondary winding has a positive polarity at the dot and D1 is conducting. When M4 ceases to conduct, the injected voltage 17 of the source 15 produces a voltage 18 in the secondary winding with a low amplitude and negative polarity at the dot. This will force the current out of D1 and into D2. Without the injected voltage 16 the current through Lo would be equally split between D1 and D2.

At the time when M1 will be turned off and M2 will be turned on, the voltage induced in the secondary winding will change polarity, creating a negative voltage at the dot. This will not change the current flow in the secondary, because D2 is already in full conduction. Without the injected voltage at this time both D1 and D2 would be in full conduction and the negative voltage induced in the secondary

winding would be applied to D1 leading to reverse recovery current and as a result reverse recovery losses.

In Fig. 3A is presented the implementation circuit. The additional injected voltage is implemented by using a small additional transformer 20 in series with the primary winding and an 5 additional capacitor 22. In Fig. 3B the key waveforms are also depicted. The additional magnetic element 20, which has the primary winding in series with the primary winding of the transformer and the secondary winding in series with the capacitor 22, accomplishes several tasks. First it creates the AC signal in series with the primary winding which forces the output rectifier out of conduction during the dead time, before the voltage polarity reverses in the secondary preventing the reverse recovery losses. The second effect is the creation of an additional triangular current injected at the connection between M1 and M2, ensuring zero voltage switching conditions even at light load.

Furthermore, in Fig. 4, the diodes D1 and D2 are replaced with synchronous rectifiers. One of the limitations associated with synchronous rectification is the conduction of the body diode, when the synchronous rectifier is turned off before the voltage polarity changes. In this way the current will flow through the body diode when the polarity changes in the secondary. The reverse recovery characteristics of the body diode are worse than ultra fast rectifiers. The advantage of a lower voltage drop on the rectifier means is offset by the additional reverse recovery losses. This problem will get worse in higher voltage applications; larger than 24V, wherein the reverse recovery loss mechanism is the dominant rectification loss. In the present invention wherein the reverse recovery losses are eliminated, it is very 20 beneficial to replace the diodes with synchronous rectifiers.

The foregoing descriptions of at least one preferred embodiment are exemplary and intended to limit the claimed invention. Obvious modifications that do not depart from the spirit and scope of the invention as claimed will be apparent to those skilled in the art.

I claim:

1. 1. A power conversion circuit having a power transformer, four semiconductor switching elements connected as a bridge across an input to the power conversion circuit and connected to a primary winding of the power transformer to reverse current through the primary winding, a split secondary winding on the power transformer, a first unidirectional current conducting device connected from one end of the split secondary winding to an inductor, a second unidirectional current conducting device connected from a second end of the split secondary winding to the inductor, the inductor and a connection to an interconnection between two halves of the split secondary winding being connected to an output of the power conversion circuit, an injection voltage source connected to the primary winding of the power transformer for applying an injection voltage to the primary winding in addition to an input voltage to the primary winding via the semiconductor switching elements connected to a bridge.
2. 2. The power conversion circuit according to claim 1, wherein the injection voltage source is a winding on an injection voltage transformer, said winding being connected in series with said primary winding of the power transformer.
3. 3. The power conversion circuit according to claim 2, wherein the injection voltage transformer has a further winding connected to a capacitor.
4. 4. The power conversion circuit according to claim 1, wherein the unidirectional current conducting devices are semiconductor switching devices.
